Lucrative Late Lambda Lifting

Sebastian Graf

October 23, 2018

1 Introduction

2 Transformation

Lambda lifting is a well-known technique [2]. Although Johnsson's original algorithm runs in wort-case cubic time relative to the size of the input program, Morazán and Schultz [5] gave an algorithm that runs in $\mathcal{O}(n^2)$.

Our lambda lifting transformation is unique in that it operates on terms of the *spineless tagless G-machine* (STG) [1] as currently implemented [3] in GHC. This means we can assume that the nesting structure of bindings corresponds to the condensation (the directed acyclic graph of strongly connected components) of the dependency graph. Additionally, every binding in a (recursive) **let** binding is annotated with the free variables it closes over. The combination of both properties allows efficient construction of the set of *required* variables for a total complexity of $\mathcal{O}(n^2)$, as we shall see.

less detail? less language?

any better names? former free variables, abstraction variables...

Shall we? Analysis performance doesn't seem to be a problem thus far

2.1 Syntax

Although STG is but a tiny language compared to typical surface languages such as Haskell, its definition [3] still contains much detail irrelevant to lambda lifting. As can be seen in fig. 1, we therefore adopt a simple lambda calculus with **let** bindings as in Johnsson [2], with a few STG-inspired features:

1. **let** bindings are annotated with the non-top-level free variables of the right-hand side (RHS) they bind
2. Every lambda abstraction is the right-hand side of a **let** binding
3. Arguments and heads in an application expression are all atomic (e.g., variable references)

We decomposed **let** expressions into smaller syntactic forms for the simple reason that it allows the analysis and transformation to be defined in more granular (and thus more easily understood) steps.

$$
\begin{array}{rll}
\text{Variables} & f, x, y & \\
\text{Expressions} & e ::= x & \text{Variable} \\
& \mid\ f\ x_1 \ldots x_n & \text{Function call} \\
& \mid\ \textbf{let}\ b\ \textbf{in}\ e & \text{Recursive } \textbf{let} \\
\text{Bindings} & b ::= \overline{f_i = [x_{i,1} \ldots x_{i,n_i}]\, r_i} & \\
\text{Right-hand sides} & r ::= \lambda y_1 \ldots y_m \to e &
\end{array}
$$

Figure 1: An STG-like untyped lambda calculus

2.2 Algorithm

Our implementation extends the original formulation of Johnsson [2] to STG terms, by exploiting and maintaining closure annotations. We will recap our variant of the algorithm in its whole here. It is assumed that all variables have unique names and that there is a sufficient supply of fresh names from which to draw.

We'll define a side-effecting function, lift, recursively over the term structure. This is its signature:

Take inspiration in "Implementing functional languages: a tutorial" and collect super-combinators afterwards for better separation of concerns. Is that possible? After all, that would influence the lifting decision!

$$\mathsf{lift}\_(\_) : \mathsf{Expander} \to \mathsf{Expr} \to \mathcal{W}_{\mathsf{Bind}}\, \mathsf{Expr}$$

As its first argument, lift takes an Expander, which is a partial function from lifted binders to their sets of required variables. These are the additional variables we have to pass at call sites after lifting. The expander is extended every time we decide to lambda lift a binding. It plays a similar role as the E_f set in Johnsson [2]. We write $\mathsf{dom}\,\alpha$ for the domain of the expander α and $\alpha[x \mapsto S]$ to denote extension of the expander function, so that the result maps x to S and all other identifiers by delegating to α.

The second argument is the expression that is to be lambda lifted. A call to lift results in an expression that no longer contains any bindings that were lifted. The lifted bindings are emitted as a side-effect of the *writer monad*, denoted by $\mathcal{W}_{\mathsf{Bind}\ \_}$.

Why not formulate this as inference rules?

I think the occurrences of body expression etc. need to be meta-variables.

2.2.1 Side-effects

The following syntax, inspired by *idiom brackets* [4] and *bang notation*[1], will

Properly define the structure? Or is this 'obvious'?

allow concise notation while hiding sprawling state threading:

$$[\![E[\langle e_1 \rangle, ..., \langle e_n \rangle]]\!]$$

This denotes a side-effecting computation that, when executed, will perform the side-effecting subcomputations e_i in order (any fixed order will do for us). After that, it will lift the otherwise pure context E over the results of the subcomputations.

In addition, we make use of the monadic bind operators $\gg=$ and $\gg$, defined in the usual way. The primitive operation note takes as argument a binding group and merges its bindings into the contextual binding group tracked by the writer monad.

2.2.2 Variables

Let's begin with the variable case.

$$\mathsf{lift}_\alpha(x) = \begin{cases} [\![x]\!], & x \notin \mathsf{dom}\,\alpha \\ [\![x\ y_1 \ldots y_n]\!], & \alpha(x) = \{y_1, \ldots, y_n\} \end{cases}$$

We check if the variable was lifted to top-level by looking it up in the supplied expander mapping α and if so, we apply it to its newly required variables. There are no bindings occuring that could be lambda lifted, hence the function performs no actual side-effects.

2.2.3 Applications

Handling function application correctly is a little subtle, because only variables are allowed in argument position. When such an argument variable's binding is lifted to top-level, it turns into a non-atomic application expression, violating the STG invariants. Each such application must be bound to an enclosing **let** binding [2]:

$$\mathsf{lift}_\alpha(f\ x_1 \ldots x_n) = [\![(\mathsf{wrap}_\alpha(x_n) \circ \ldots \circ \mathsf{wrap}_\alpha(x_1))(\langle \mathsf{lift}_\alpha(f) \rangle\ x'_1 \ldots x'_n)]\!]$$

The notation x' chooses a fresh name for x in a consistent fashion. The application head f is handled by an effectful recursive call to lift. Syntactically heavy **let** wrapping is outsourced into a helper function wrap:

$$\mathsf{wrap}_\alpha(x)(e) = \begin{cases} \textbf{let}\ x' = [x]\lambda \to x\ \textbf{in}\ e, & x \notin \mathsf{dom}\,\alpha \\ \textbf{let}\ x' = [\,]\lambda y_1 \ldots y_n \to x\ y_1 \ldots y_n\ \textbf{in}\ e, & \alpha(x) = \{y_1, \ldots, y_n\} \end{cases}$$

The application rule is unnecessarily complicated because we support occurrences of lifted binders in argument position. Lifting such binders isn't worthwhile anyway (see section 3). Maybe just say that we don't allow it?

[1] http://docs.idris-lang.org/en/v1.3.0/tutorial/interfaces.html

[2] To keep the specification reasonably simple, we also do so for non-lifted identifiers and assume that the compiler can do the trivial rewrite **let** $y = [x]\lambda \to x$ **in** $E[y] \Longrightarrow E[x]$ for us.

2.2.4 Let Bindings

Hardly surprising, the meat of the transformation hides in the handling of **let** bindings. This can be broken down into three separate functions:

$$\mathsf{lift}_\alpha(\textbf{let } bs \textbf{ in } e) = (\mathsf{recurse}(e) \circ \mathsf{decide\text{-}lift}_\alpha \circ \mathsf{expand\text{-}closures}_\alpha)(bs)$$

1. The first step is to expand closures mentioned in *bs* with the help of α.
2. Second, a heuristic (that of section 3, for example) decides whether to lift the binding group *bs* to top-level or not.
3. Depending on that decision, the binding group is noted to be lifted to top-level and syntactic subentities of the **let** binding are traversed with the updated expander.

$$\mathsf{expand\text{-}closures}_\alpha(\overline{f_i = [x_1 \dots x_{n_i}]r_i}) = \overline{f_i = [y_1 \dots y_{n'_i}]r_i}$$

where

$$\{y_1 \dots y_{n'_i}\} = \bigcup_{j=1}^{n_i} \begin{cases} x_j, & x_j \notin \mathsf{dom}\,\alpha \\ \alpha(x_j), & \text{otherwise} \end{cases}$$

expand-closures substitutes all occurences of lifted binders (those that are in $\mathsf{dom}\,\alpha$) in closures of a given binding group by their required set.

Not happy with the indices. $y_{i,1}$ maybe? Applies to many more examples.

$$\mathsf{decide\text{-}lift}_\alpha(bs) = \begin{cases} (\varepsilon, \alpha', \mathsf{lambda\text{-}lift}_{\alpha'}(bs)), & \text{if } bs \text{ should be lifted} \\ (bs, \alpha, \varepsilon), & \text{otherwise} \end{cases}$$

where

$$\alpha' = \alpha \left[\overline{f_i \mapsto \mathsf{fvs}(bs)}\right] \text{ for } \overline{f_i = [\_]\_} = bs$$

decide-lift returns a triple of a binding group that remains with the local **let** binding, an updated expander and a binding group prepared to be lifted to top-level. Depending on whether the argument *bs* is decided to be lifted or not, either the returned local binding group or the lambda-lifted binding group is empty. In case the binding is to be lifted, the expander is updated to map the newly lifted bindings to their required set.

$$\mathsf{fvs}(\overline{f_i = [x_1 \dots x_{n_i}]\_}) = \bigcup_i \{x_1, \dots, x_{n_i}\} \setminus \overline{f_i}$$

The required set consists of the free variables of each binding's RHS, conveniently available in syntax, minus the defined binders themselves. Note that the required set of each binder of the same binding group will be identical.

$$\mathsf{lambda\text{-}lift}_\alpha(\overline{f_i = [x_1 \ldots x_{n_i}]\lambda y_1 \ldots y_{m_i} \to e_i}) = \overline{f_i = []\lambda\alpha(f_i)\ y_1 \ldots y_{m_i} \to e_i}$$

The syntactic lambda lifting is performed in lambda-lift, where closure variables are removed in favor of a number of parameters, one for each element of the respective binding's required set.

"Implementing functional languages: a tutorial" calls this the *abstraction step.*

$$\mathsf{recurse}(e)(bs, \alpha, lbs) = \mathsf{lift\text{-}bind}_\alpha(lbs) \gg\!= \mathsf{note} \gg [\![\textbf{let}\ \langle \mathsf{lift\text{-}bind}_\alpha(bs)\rangle\ \textbf{in}\ \langle \mathsf{lift}_\alpha(e)\rangle]\!]$$

In the final step of the **let** "pipeline", the algorithm recurses into every subexpression of the **let** binding. The binding group to be lifted is transformed first, after which it is added to the contextual top-level binding group of the writer monad. Finally, the binding group that remains locally bound is traversed, as well as the original **let** body. The result is again wrapped up in a **let** and returned[3].

What remains is the trivial, but noisy definition of the lift-bind traversal:

$$\mathsf{lift\text{-}bind}_\alpha(\overline{f_i = [x_1 \ldots x_{n_i}]\lambda y_1 \ldots y_{m_i} \to e_i}) = [\![\overline{f_i = [x_1 \ldots x_{n_i}]\lambda y_1 \ldots y_{m_i} \to \langle \mathsf{lift}_\alpha(e_i)\rangle}]\!]$$

3 When to lift

Lambda lifting a binding to top-level is always a sound transformation. The challenge is in identifying *when* it is beneficial to do so. This section will discuss operational consequences of lambda lifting, introducing multiple criteria based on a cost model for estimating impact on heap allocations.

We'll take a somewhat loose approach to following the STG invariants in our examples (regarding giving all complex subexpressions a name, in particular), but will point out the details if need be.

3.1 Syntactic consequences

Deciding to lift a binding **let** $f = [x\ y\ z]\lambda a\ b\ c \to e_1$ **in** e_2 to top-level has the following consequences:

(S1) It eliminates the **let** binding.

(S2) It creates a new top-level definition.

(S3) It replaces all occurrences of f in e_2 by an application of the lifted top-level binding to its former free variables, replacing the whole **let** binding by the term $[f \mapsto f_\uparrow\ x\ y\ z]\ e_2$.[4]

[3] Similar to the application case, we assume that the compiler performs the obvious rewrite **let** ε **in** $e \Longrightarrow e$.

[4] Actually, this will also need to give a name to new non-atomic argument expressions (cf. section 2.2.3). We'll argue shortly that there is hardly any benefit in allowing these cases.

(S4) All non-top-level variables that occurred in the **let** binding's right-hand side become parameter occurrences.

Naming seemingly obvious things this way means we can precisely talk about *why* we are suffering from one of the operational symptoms discussed next.

3.2 Operational consequences

We now ascribe operational symptoms to combinations of syntactic effects. These symptoms justify the derivation of heuristics which will decide when *not* to lift.

Argument occurrences. Consider what happens if f occurred in the **let** body e_2 as an argument in an application, as in $g\ 5\ x\ f$. (S3) demands that the argument occurrence of f is replaced by an application expression. This, however, would yield a syntactically invalid expression because the STG language only allows trivial arguments in an application.

The transformation from section 2 will immediately wrap the application in a **let** binding for the complex argument expression: $g\ 5\ x\ f \Longrightarrow$ **let** $f' = f_\uparrow\ x\ y\ z$ **in** $g\ 5\ x\ f'$. But this just reintroduces at every call site the very allocation we wanted to eliminate through lambda lifting! Therefore, we can identify a first criterion for non-beneficial lambda lifts:

(C1) Don't lift binders that occur as arguments

A welcome side-effect is that the application case of the transformation in section 2.2.3 becomes much simpler: The complicated wrap business becomes unnecessary.

Closure growth. (S1) means we don't allocate a closure on the heap for the **let** binding. On the other hand, (S3) might increase or decrease heap allocation, which can be captured by a metric we call *closure growth*. Consider this example:

let $f = [x\ y]\lambda a\ b \to ...$
  $g = [f\ x]\lambda d \to f\ d\ d + x$
in $g\ 5$

Should f be lifted? It's hard to say without actually seeing the lifted version:

$f_\uparrow = \lambda x\ y\ a\ b \to ...;$
let $g = [x\ y]\lambda d \to f_\uparrow\ x\ y\ d\ d + x$
in $g\ 5$

Just counting the number of variables occurring in closures, the effect of (S1) saved us two slots. At the same time, (S3) removes f from g's closure (no need to close over the top-level $f_\uparrow$), while simultaneously enlarging it with f's former free variable y. The new occurrence of x doesn't contribute to closure growth, because it already occurred in g prior to lifting. The net result is a reduction of two slots, so lifting f seems worthwhile. In general:

(C2) Don't lift a binding when doing so would increase closure allocation

Note that this also includes handling of **let** bindings for partial applications that are allocated when GHC spots an undersaturated call.

Estimation of closure growth is crucial to identifying beneficial lifting opportunities. We discuss this further in section 3.3.

Calling Convention. (S4) means that more arguments have to be passed. Depending on the target architecture, this entails more stack accesses and/or higher register pressure. Thus

(C3) Don't lift a binding when the arity of the resulting top-level definition exceeds the number of available argument registers of the employed calling convention (e.g., 5 arguments for GHC on x86_64)

One could argue that we can still lift a function when its arity won't change. But in that case, the function would not have any free variables to begin with and could just be floated to top-level. As is the case with GHC's full laziness transformation, we assume that this already happened in a prior pass.

Turning known calls into unknown calls. There's another aspect related to (S4), relevant in programs with higher-order functions:

$$\begin{array}{l}\textbf{let } f = [\,]\lambda x \to 2 * x \\ \quad \mathit{mapF} = [f]\lambda \mathit{xs} \to ...f\ x\ ... \\ \textbf{in } \mathit{mapF}\ [1,2,3]\end{array}$$

Here, there is a *known call* to f in mapF that can be lowered as a direct jump to a static address [3]. Lifting mapF (but not f) yields the following program:

$$\begin{array}{l}\mathit{mapF}_{\uparrow} = \lambda f\ \mathit{xs} \to ...f\ x...; \\ \textbf{let } f = [\,]\lambda x \to 2 * x \\ \textbf{in } \mathit{mapF}_{\uparrow}\ f\ [1,2,3]\end{array}$$

(C4) Don't lift a binding when doing so would turn known calls into unknown calls

Code size. (S2) (and, to a lesser extent, all other consequences) have the potential to increase or decrease code size. We regard this a secondary concern, but will have a look at it in section 4.

Sharing. Let's finish with a no-brainer: Lambda lifting updatable bindings (e.g., thunks) or constructor bindings is a bad idea, because it destroys sharing, thus possibly duplicating work in each call to the lifted binding.

(C5) Don't lift a binding that is updatable or a constructor application

3.3 Estimating Closure Growth

Of the criterions above, (C2) is the most important for reliable performance gains. It's also the most sophisticated, because it entails estimating closure growth.

3.3.1 Motivation

Let's revisit the example from above:

```
let f = [x y]λa b → ...
    g = [f x]λd → f d d + x
in g 5
```

We concluded that lifting f would be beneficial, saving us allocation of two free variable slots. There are two effects at play here. Not having to allocate the closure of f due to (S1) always leads to a one-time benefit. Simultaneously, each closure occurrence of f would be replaced by its referenced free variables. Removing f leads to a saving of one slot per closure, but the free variables x and y each occupy a closure slots in turn. Of these, only y really contributes to closure growth, because x already occurred in the single remaining closure of g.

This phenomenon is amplified whenever allocation happens under a multi-shot lambda, as the following example demonstrates:

```
let f = [x y]λa b → ...
    g = [f x]λd →
      let h = [f]λe → f e e
      in h d
in g 1 + g 2 + g 3
```

Is it still beneficial to lift f? Following our reasoning, we still save two slots from f's closure, the closure of g doesn't grow and the closure h grows by one. We conclude that lifting f saves us one closure slot. But that's nonsense! Since g is called thrice, the closure for h also gets allocated three times relative to single allocations for the closures of f and g.

In general, h might be occuring inside a recursive function, for which we can't reliably estimate how many times its closure will be allocated. Disallowing to lift any binding which is called inside a closure under such a multi-shot lambda is conservative, but rules out worthwhile cases like this:

```
let f = [x y]λa b → ...
    g = [f x y]λd →
      let h1 = [f]λe → f e e
          h2 = [f x y]λe → f e e + x + y
      in h1 d + h2 d
in g 1 + g 2 + g 3
```

Here, the closure of h_1 grows by one, whereas that of h_2 shrinks by one, cancelling each other out. Hence there is no actual closure growth happening under the multi-shot binding g and f is good to lift.

The solution is to denote closure growth in the (not quite max-plus) algebra $\mathbb{Z}_\infty = \mathbb{Z} \cup \{\infty\}$ and denote positive closure growth under a multi-shot lambda by ∞.

3.3.2 Design

Applied to our simple STG language, we can define a function cl-gr (short for closure growth) with the following signature:

Maybe add the syntactic sort we operate on as a superscript?

$$\mathsf{cl\text{-}gr}\_\_(\_) \colon \mathcal{P}(\mathsf{Var}) \to \mathcal{P}(\mathsf{Var}) \to \mathsf{Expr} \to \mathbb{Z}_\infty$$

Given two sets of variables for added and removed closure variables, respectively, it maps expressions to the closure growth resulting from

- adding variables from the first set everywhere a variable from the second set is referenced
- and removing all closure variables mentioned in the second set.

In the lifting algorithm from section 2, cl-gr would be consulted as part of the lifting decision to estimate the total effect on allocations. Assuming we were to decide whether to lift the binding group $\overline{f_i}$ out of an expression $\textbf{let } \overline{f_i = [x_1 \dots x_{n_i}]\lambda y_1 \dots y_{m_i} \to e_i} \textbf{ in } e$, the following expression conservatively estimates the effects on heap allocation for performing the lift:

$$\mathsf{cl\text{-}gr}_{\alpha'(f_1)\,\{\overline{f_i}\}}(\textbf{let } \overline{f_i = [\,]\lambda x_1 \dots x_{n_i} y_1 \dots y_{m_i} \to e_i} \textbf{ in } e) - \sum_i n_i$$

With the *required set* $\alpha'(f_1)$ passed as the first argument and with $\{\overline{f_i}\}$ for the second set (i.e. the binders for which lifting is to be decided).

Note that we logically lambda-lifted the binding group in question without actually floating out the binding. The reasons for that are twofold: Firstly, the reductions in closure allocation resulting from that lift are accounted separately in the trailing sum expression, capturing the effects of (S1). Secondly, the lifted binding group isn't affected by closure growth (where there are no free variables, nothing can grow or shrink), which is entirely a symptom of (S3).

In practice, we require that this metric is non-positive to allow the lambda lift.

3.3.3 Implementation

The cases for variables and applications are trivial, because they don't allocate:

$$\mathsf{cl\text{-}gr}_{\varphi^+\varphi^-}(x) = 0$$
$$\mathsf{cl\text{-}gr}_{\varphi^+\varphi^-}(f\ x_1 \dots x_n) = 0$$

As before, the complexity hides in **let** bindings and its syntactic components. We'll break them down one layer at a time. This makes the **let** rule itself nicely compositional, because it delegates most of its logic to cl-gr-bind:

$$\mathsf{cl\text{-}gr}_{\varphi^+\varphi^-}(\textbf{let } bs \textbf{ in } e) = \mathsf{cl\text{-}gr\text{-}bind}_{\varphi^+\varphi^-}(bs) + \mathsf{cl\text{-}gr}_{\varphi^+\varphi^-}(e)$$

Next, we look at how binding groups are measured:

$$\mathsf{cl\text{-}gr\text{-}bind}_{\varphi^+\varphi^-}(\overline{f_i = [x_1 \ldots x_{n_i}]\, r_i}) = \sum_i \mathsf{growth}_i + \sum_i \mathsf{cl\text{-}gr\text{-}rhs}_{\varphi^+\varphi^-}(r_i)$$

$$\mathsf{growth}_i = \begin{cases} |\varphi^+ \setminus \{x_1, \ldots, x_{n_i}\}| - \nu_i, & \text{if } \nu_i > 0 \\ 0, & \text{otherwise} \end{cases}$$

$$\nu_i = \left|\{x_1, \ldots, x_{n_i}\} \cap \varphi^-\right|$$

The growth component accounts for allocating each closure of the binding group. Whenever a closure mentions one of the variables to be removed (i.e. φ^-, the bindings to be lifted), we count the number of variables that are removed in ν and subtract them from the number of variables in φ^+ (i.e. the required set of the binding group to lift) that didn't occur in the closure before.

The call to cl-gr-rhs accounts for closure growth of right-hand sides:

$$\mathsf{cl\text{-}gr\text{-}rhs}_{\varphi^+\varphi^-}(\lambda \ldots \to e_i) = \mathsf{cl\text{-}gr\text{-}rhs}_{\varphi^+\varphi^-}(r_i) * [\sigma, \tau]$$

$$\sigma = \begin{cases} 1, & e \text{ is entered at least once} \\ 0, & \text{otherwise} \end{cases}$$

$$\tau = \begin{cases} 0, & e \text{ is never entered} \\ 1, & e \text{ is entered at most once} \\ 1, & \text{the RHS is bound to a thunk} \\ \infty, & \text{otherwise} \end{cases}$$

$$n * [\sigma, \tau] = \begin{cases} n * \sigma, & l < 0 \\ n * \tau, & \text{otherwise} \end{cases}$$

The right-hand sides of a **let** binding might or might not be entered, so we cannot rely on a beneficial negative closure growth to occur in all cases. Likewise, without any further analysis information, we can't say if a right-hand side is entered multiple times. Hence, the uninformed conservative approximation would be to return ∞ whenever there is positive closure growth in a RHS and 0 otherwise.

That would be disastrous for analysis precision! Fortunately, GHC has access to cardinality information from its demand analyser . Demand analysis estimates lower and upper bounds (σ and τ above) on how many times a RHS is entered relative to its defining expression.

Most importantly, this identifies one-shot lambdas ($\tau = 1$), under which case a positive closure growth doesn't lead to an infinite closure growth for the whole RHS. But there's also the beneficial case of negative closure growth under a strictly called lambda ($\sigma = 1$), where we gain precision by not having to fall back to returning 0.

What to cite? Progress on the new demand analysis paper seemed to have stalled. The cardinality paper? The old demand analysis paper from 2006? Both?

One final remark regarding analysis performance: cl-gr operates directly on STG expressions. This means the cost function has to traverse whole syntax trees *for every lifting decision*.

We remedy this by first abstracting the syntax tree into a *skeleton*, retaining only the information necessary for our analysis. In particular, this includes allocated closures and their free variables, but also occurrences of multi-shot lambda abstractions. Additionally, there are the usual "glue operators", such as sequence (e.g., the case scrutinee is evaluated whenever one of the case alternatives is), choice (e.g., one of the case alternatives is evaluated *mutually exclusively*) and an identity (i.e. literals don't allocate). This also helps to split the complex **let** case into more manageable chunks.
